

# Quantum Walks and Resetting

Dhruva Sambrani

*A dissertation submitted for the partial fulfilment of BS-MS dual  
degree in Science*

Indian Institute of Science Education and Research, Mohali

2023-04-02

# Certificate of Examination

This is to certify that the dissertation titled **Quantum Walks and Resetting** submitted by **Dhruva Sambrani** (Reg. No. MS18163) for the partial fulfillment of BS- MS Dual Degree programme of the institute, has been examined by the thesis committee duly appointed by the institute. The committee finds the work done by the candidate satisfactory and recommends that the report be accepted.

Dr. Manabendra Nath Bera

Dr. Abhishek Chaudhary

Dr. Sandeep Goyal

Dr. Manabendra Nath Bera  
(Supervisor)

Dated: 2023-04-02

## Declaration

The work presented in this dissertation has been carried out by me under the guidance of Dr. Manabendra Nath Bera at the Indian Institute of Science Education and Research, Mohali.

This work has not been submitted in part or in full for a degree, a diploma, or a fellowship to any other university or institute. Whenever contributions of others are involved, every effort is made to indicate this clearly, with due acknowledgement of collaborative research and discussions. This thesis is a bonafide record of original work done by me and all sources listed within have been detailed in the bibliography.

Dhruva Sambrani  
(Candidate)  
Dated: 2023-04-02

In my capacity as the supervisor of the candidates project work, I certify that the above statements by the candidate are true to the best of my knowledge.

Dr. Manabendra Nath Bera  
(Supervisor)  
Dated: 2023-04-02

# Abstract

While quantum walks are faster than their classical counterparts in searching a node, the transient nature of quantum walks leads to a non-zero failure rate. By classically resetting the walk, it has been shown that the walk can be made recurrent, and thus the asymptotic failure rate goes to 0 without sacrificing the quantum speedup. In this work, we attempt to define a quantum resetting mechanism, and probe its effect on the mean hit time of the walk.

First we propose a controlled reset-evolve operation, drawing inspiration from the coined quantum walk formalism. We show computationally, that for a range of parameters, there is no apparent speed up gained by this protocol. Furthermore, an additional coin and non-unitary operation set renders the protocol difficult to analyse. Thus, we require a quantum reset mechanism which remains unitary.

This brings us to our second resetting proposal based on Szegedy walks. Using the Szegedy walk formalism, we can quantise the stochastic reset classical walk, thereby achieving a unitary quantum reset protocol. We further show computationally that a speedup for the Grover-like search protocol is achieved by the unitary reset walk for a range of parameters. We also use eigenvalue analysis to analyse the space and time complexity of protocol, and show a clear advantage in running the protocol.

# Introduction

Random walks are a commonly used tool in the arsenal of algorithms on Classical Computers to solve a variety of problems which do not have a known easy solution. The power of such methods can be attributed to the fact that while the space of possible solutions is vast, we only need to sample few solutions to come to a close solution. This power has been routinely exploited in the past to sample from Markov Chains using the MCMC algorithm which can be found in any introductory textbook<sup>1</sup> of Markov processes, and they have recently been used in the fields of Financial engineering<sup>2</sup>, fluid mechanics<sup>3</sup>, fitting black hole images<sup>4</sup> and most famously in the Los Alamos project<sup>5</sup>.

With the advent of quantum algorithms, quantum walks have arisen as an obvious extension of classical walks in the quantum domain. The applications of quantum walks are just as many: ANN training<sup>6</sup>, Random Number Generation<sup>7</sup>, List coloring (Grover)<sup>8</sup>, collision finding<sup>9</sup>, link prediction<sup>10</sup>. There has even been a recent foray into classifying and using a quantum-classical walk to speed up certain classical algorithms, namely the Google PageRank Algorithm<sup>11</sup>. The increased interest in quantum walks can be attributed to the quadratic speed up which it grants the solution a-la the Grover algorithm, which itself can be considered as a Quantum Walk<sup>12</sup>.

In this master thesis, we will first define the classical (Chapter 1) walk, and specifically, the 1D walk. The classical 1D walk has a standard deviation which goes as  $\mathcal{O}(T^{1/2})$ , and is recurrent.

Then we define quantum (Chapter 2) walk, particularly the coined walk on a 1D grid. The quantum 1D walk has a standard deviation which goes as  $\mathcal{O}(T)$ , and is transient.

We define these walks with a view of using these walks in search algorithms. We formalise the search problem and show how the quantum walk is faster but its transient nature leads to a non zero asymptotic failure rate in Chapter 3.

Then, we look at previous attempts at solving them by resetting (Chapter 4). By resetting a markov chain, we can convert a transient chain to a recurrent one. We explore the effect of resetting in the quantum case, attempting to recreate past work in continuous time quantum walks in the discrete time quantum walks. We also look at possible shortcomings of the solution.

In Chapter 5, we introduce a new mechanism for quantum resetting based on superposition of the evolution and reset operations and show numerically that it does not have advantage in the search problem (Chapter 5). However, we propose possible methods to analyze this setup and leave it for a future project.

Finally, we introduce a second protocol for reset quantum walks by quantizing the Markov process via Szegedy walks (Chapter 6). We also present a Grover like search

algorithm, which is easily analyzable by eigenvalue analysis. The results and discussions of this protocol are presented in Chapter [7](#).

We then conclude and provide future directions of this work in the summary

Along with the theory, certain aspects of the implementation of the walks computationally are also added as necessary. This is done inline instead of in an appendix, which is the norm, since the author believes that such a presentation solidifies the readers' understanding of both, the model and the implementation. We use Julia<sup>[13](#)</sup> and its standard libraries, Plots.jl<sup>[14](#)</sup>, QuantumInformation.jl<sup>[15](#)</sup>, Luxor.jl<sup>[16](#)</sup>, Yao.jl and YaoPlots.jl<sup>[17](#)</sup>.

# 1. Classical Walks

Classical random walks are defined on a graph, with the walker being on some initial node  $i_0$  with a probability  $\lambda_i$ , and “hopping” from node  $i$  to  $j$  in each time step with a probability given by  $p_{ij}$ . We can thus define a transition matrix  $P := P_{ij} = p_{ij}$  which is row stochastic. Thus the probability mass function of the walker at time step  $t$  is given by  $\lambda P^t$ . Of course, the exact structure of the graph and the probabilities will decide the properties of the walk and there exists a vast amount of literature devoted to this analysis.

We however will restrict our discussion to the symmetric walk on the 1D chain. This is often called the 1D-Simple Symmetric Random Walk, and defined in the following way.

## 1.1. Definition

Consider an infinite 1 D chain, with nodes marked by  $\mathbb{Z}$ .

Figure 1.1.: 1 D Chain

Define the probability of hopping from node  $i$  to node  $j$

$$p_{ij} = \begin{cases} 1/2 & |i - j| = 1 \\ 0 & \text{otherwise} \end{cases}$$

And the initial state as

$$\lambda_{ij} = \begin{cases} 1 & i = 0 \\ 0 & \text{otherwise} \end{cases}$$

Thus, the hopper can only move to it nearest neighbors, starting from node 0.

Note that  $P(X_t = i | \text{HISTORY}) = P(X_t = i | X_{t-1})$ , which means that the walk is a Markov chain.

## 1.2. Multiple Walkers

The SSRW is clearly a stochastic process, and each run of this process will lead to different paths being chosen by the walker, and we are more interested in what the walker does on an average rather than what happens in a particular instance. Thus, we can observe multiple walks, and plot their paths to visualize how they would spread.

In order to simulate a walk, we sample  $X_i \in \{-1, 1\}$  with equal probability, and add it to the previous position  $S_{i-1}$  to get  $S_i$ . Note  $S_0 = 0$ . Thus, this is equivalent to sampling from  $[1, -1]$  uniformly  $t$  times and performing a cumulative sum. For  $n$  walkers, we can sample  $(t, n)$  such random numbers, and do a cumulative sum along the first dimension.

```
bm = cumsum(rand([1, -1], (200, 15)), dims=1);
```

Figure 1.2.: An ensemble of classical walkers

## 1.3. Probability mass function

Another common way to visualize the walk is to plot the probability that the walker is on node  $i$  at time  $t$ . For this, we define the transition matrix and  $\lambda$  appropriately and find  $\lambda P^t$ . Note however that the transition matrix for the SSRW is Tridiagonal with the Upper and Lower diagonals as 0.5 and the diagonal as 0, and there exist efficient

storage and multiplication routines. Also, since we can only store a finite matrix, we limit the walk to some size. At the boundaries, we set open conditions, because this is the easiest to implement.

```
cps, cps_t = let
  t = 21
  U = SymTridiagonal(fill(0., 31), fill(0.5, 30))
  λ = fill(0., 31)
  λ[16] = 1
  ps = accumulate(1:t, init=λ) do old, _
    U * old
  end[t÷3:t÷3:t], t÷3
end;
```

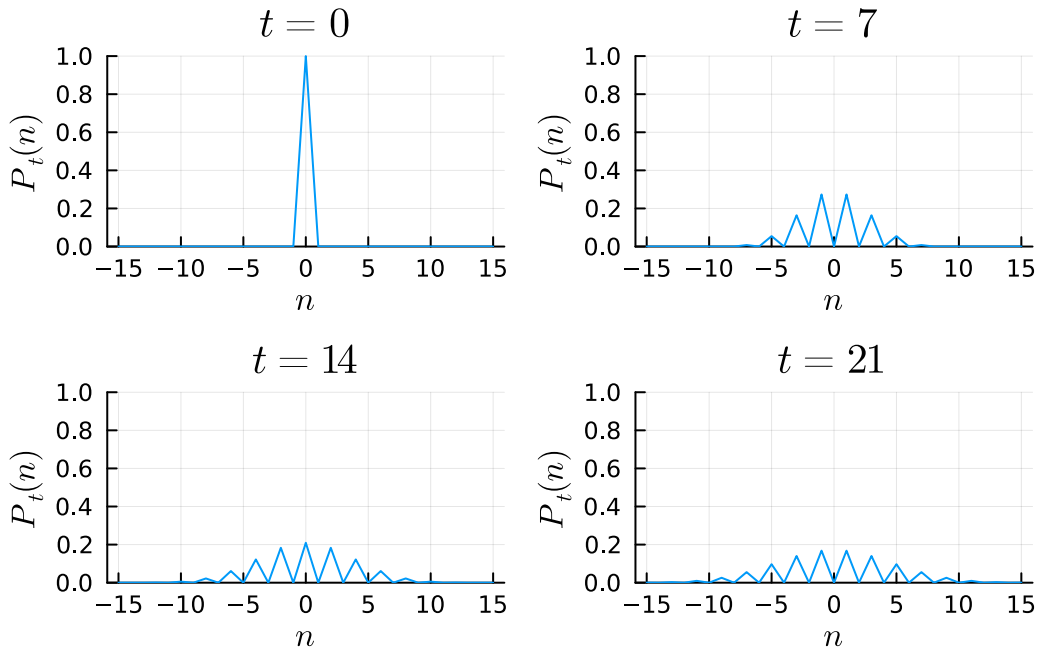

Figure 1.3.: Probability distribution of a classical walker in time

## 1.4. Properties of the walk

Certain properties of the walk that are interesting for the problem we pose in the subsequent sections. Primarily, we are interested in the mean, standard deviation and recurrence of the graph.

The probability that a walker is on node  $n$  at time  $t$  is given by the expression

$$p(n, t) = \binom{t}{\frac{t+n}{2}} \frac{1}{2^t}$$

This equation is valid only if  $t + n$  is even and  $n \leq t$ . If  $t + n$  is odd or  $n > t$ , the probability is zero

It should be obvious from the even symmetry of  $p(n, t)$  that the mean  $\mu(t) = \sum_n np(n, t) = 0$ . This comes from the fact that the walk is symmetric.

The standard deviation of the walker position  $\sigma(t) = \sqrt{\langle n^2 \rangle - \langle n \rangle^2} = \sqrt{\sum_n n^2 p(n, t)} = \sqrt{t}$ <sup>18</sup>.

## 2. Quantum Walks

### 2.1. Introduction

Quantum walks are defined analogous to the classical walks.

First, our walker is quantum mechanical, and the position of the walker can be a superposition of the nodes. Thus, we define the state of the walker to be a superposition of the node states  $|i\rangle$ .

$$|\psi\rangle = \sum_i c_i |i\rangle$$

Let this Hilbert space be denoted as  $\mathcal{H}_W$ . The projection of the state on some node  $i$  given by  $|\langle i|\psi\rangle|^2 = |c_i|^2$  is understood as the probability that the walker will collapse to the state  $|i\rangle$  on measurement.

To define the evolution of the node, we look back at the transition matrix  $P_{ij}$ . Thus we would define an operation in the following manner -

$$O|i\rangle = \sum_j \sqrt{p_{ij}} |j\rangle$$

and the walk proceeds by repeated application of  $O$ .

While this expression is enough to define the walk, it is not immediately clear how one would explicitly realize such an operation. Multiple formalisms define such walks, but we shall use the coined quantum walk formalism which is very natural for regular graphs, as is the case for the 1D chain. Note that for the symmetric walks on nD lattices, like the 1D chain, the tight-binding model is already a well understood continuous time quantum walk. However, we prefer a discrete time formalism.

### 2.2. Coined Quantum Walk for 1D Chain

For the 1D chain, given a specific node, there are only 2 other nodes connected to it. Thus, we can add a 2 level system, which “decides” which node the walker jumps to. More formally, we attach a 2 level qubit system to the walker whose bases are denoted by  $|0\rangle$  and  $|1\rangle$ . Let us denote this Hilbert space as  $\mathcal{H}_C$

Thus, we can define the shift operation as

$$S|0\rangle|i\rangle = |0\rangle|i-1\rangle; S|1\rangle|i\rangle = |1\rangle|i+1\rangle$$

How would we define such an operation explicitly?

$$S = |0\rangle\langle 0| \otimes S_L + |1\rangle\langle 1| \otimes S_R$$

Where  $S_L$  and  $S_R$  are defined as

$$S_L|i\rangle = |i-1\rangle, S_R|i\rangle = |i+1\rangle$$

Note that  $S$  operates on  $\mathcal{H}_C \otimes \mathcal{H}_W$ , whereas  $S_L$  and  $S_R$  operate on  $\mathcal{H}_W$  only.

The superposition in the two choices at each step is recovered by putting the coin into a superposition of its basis states. This is achieved via a coin operator, which is commonly defined as  $H \otimes I$ , where  $H$  is the single qubit Hadamard operator.

Let us explicitly write down two steps of the walk

$$\begin{aligned} H \otimes I(|0\rangle|0\rangle) &= \frac{|0\rangle|0\rangle + |1\rangle|0\rangle}{\sqrt{2}} \\ S \left( \frac{|0\rangle|0\rangle + |1\rangle|0\rangle}{\sqrt{2}} \right) &= \frac{|0\rangle|-1\rangle + |1\rangle|1\rangle}{\sqrt{2}} \\ H \otimes I \frac{|0\rangle|-1\rangle + |1\rangle|1\rangle}{\sqrt{2}} &= \frac{|0\rangle|-1\rangle + |1\rangle|-1\rangle + |0\rangle|1\rangle - |1\rangle|1\rangle}{2} \\ S \frac{|0\rangle|-1\rangle + |1\rangle|-1\rangle + |0\rangle|1\rangle - |1\rangle|1\rangle}{2} &= \frac{|0\rangle|-2\rangle + (|1\rangle + |0\rangle)|0\rangle - |1\rangle|2\rangle}{2} \end{aligned}$$

#### Repeated application of Coin Operator

Note specifically the repeated application of the coin operator. If the coin operator is not applied in step 3, our state will end up in  $\frac{1}{\sqrt{2}}(|0\rangle|-2\rangle + |1\rangle|2\rangle)$  which is not what we wanted. This is because the application of the controlled shift operation entangles the coin and the walker systems, and thus there is no superposition in each term of the system

## 2.3. Computational Implementation

We show 2 ways to implement the Quantum walks, which are both interesting in their own ways. But the foremost thing to tackle would be how to store an infinite vector and an infinite dimensional operator. Since we cannot do either of these simply, we instead limit our walk to a node space of  $2n$ , and use periodic boundary conditions.

### ⚠ Other Boundary Conditions

One could pick other boundary conditions too, such as the open or the absorbing boundary conditions, but both of these BCs lead to non-unitary operations, which complicate the definition and application of the gate.

## 2.3.1. Matrix formalism

The first and more immediate method is to simply write down the matrix equivalent of the above operations. For the visualization of the implementations, we will assume that the walk occurs in a 1 D chain of size 4.

The coin is preferred to be in the  $\frac{1}{\sqrt{2}}(|0\rangle + i|1\rangle)$  when we start so that the walk proceeds symmetrically<sup>18</sup>.

```
init_coin = 1/√2 * (ket(1,2) - 1im * ket(2,2));
```

The coin operator is trivial to write,

```
H = KrausOperators([sparse(hadamard(2)⊗I(4))]);
```

The left and right shift operators can be defined in the following manner.

```
R = collect(Tridiagonal(fill(1., 3), zeros(4), zeros(3)))
R[1, end] = 1
L = collect(Tridiagonal(zeros(3), zeros(4), fill(1., 3)))
L[end, 1] = 1
```

Thus the shift operator is defined as

```
S = KrausOperators([sparse(proj(ket(1, 2)) ⊗ L + proj(ket(2, 2)) ⊗ R)]);
```

Thus, we can repeatedly apply  $S \circ H$  to the initial state and accumulate the results.

```
init_state = proj(init_coin ⊗ ket(2,4))
ψ = [[init_state]; accumulate(1:40, init=init_state) do old, _
    H(S(old))
end];
```

Now we can plot the readout statistics by partially tracing out the coin, and plotting the diagonal. The following is a walk on 61 nodes.

### ⚠ Quantum Walks are not random

Note, this is a single walker, not an ensemble of walkers as is the case in classical random walks. Quantum walks (without measurement), are completely deterministic.

Figure 2.1.: Probability distribution of a Quantum Walker in time

### 2.3.2. Circuit Formalism

While the matrix definition of the Quantum Walks are easy to formalize and understand, finally these need to be simulated on some sort of device which may require us to reformulate it. Further, we try to ensure that the reformulation allows for easy additions of other dynamics which we may want to study.

The advantages of using a Quantum Computer over a classical computer for a quantum walk should be obvious. The problem however is that the quantum walk is over a high dimensional space, and we rarely have access to such high dimensional systems which we can control easily. Instead we need to simulate such a system using the accessible 2 level systems available in quantum computers.

Let us define the basic components of our walk.

#### 2.3.2.1. Nodes

- Each numbered node is then converted into its 2-ary  $n$  length representation denoted by  $(x_i)$ .  $n$  is chosen such that  $2^n > N$
- These bitstrings are encoded into an  $n$  qubit computer, where each basis state in the computational basis corresponds to the node with the same bitstring.
- The amplitude of a particular basis corresponds to the amplitude of the walker in the corresponding node

#### 2.3.2.2. Coin

- The Walk Coin is a two level system, as usual

### 2.3.2.3. Edges and Shifts

- Since shifts are only to adjacent nodes, the left (right) shift is equivalent of subtracting (adding) 1 from the bitstring of the state.
- From the Quantum adder circuit, we can set one input to be  $(0)_{n-1}1$  and reduce the circuit to get the Quantum AddOne circuit. Shown below is the circuit for  $n = 4$  ( $N = 16$ )
- We can similarly construct the SubOne circuit, but that is simplified by noting that the SubOne circuit is simply the inverse of the AddOne circuit, and this corresponds to just inverting the circuit (all gates are unitary).

```
rightshift(n) = chain(
  n,
  map(n:-1:2) do i
    control(1:i-1, i⇒X) end...,
  put(1⇒X)
)
leftshift(n) = rightshift(n)';
```

```
YaoPlots.plot(rightshift(4))
```

Figure 2.2.: Right shift circuit

```
YaoPlots.plot(leftshift(4))
```

Figure 2.3.: Left shift circuit

The controlled shift operation is encoded as

```
shift(n) = chain(n+1,
    control(1, 2:n+1 ⇒ rightshift(n)),
    put(1 ⇒ X),
    control(1, 2:n+1 ⇒ leftshift(n)),
    put(1 ⇒ X),
)
YaoPlots.plot(shift(4))
```

Figure 2.4.: Controlled shift circuit

#### 2.3.2.4. Coin operator

We can add the coin operator as usual on the first rail.

```
coin(n, c=Yao.H) = chain(n+1, put(1 ⇒ c))
YaoPlots.plot(coin(4))
```

Figure 2.5.: Coin Operator circuit

### 2.3.2.5. Evolve Circuit

Putting these together, we get the operation for a single step of the evolution as below. Note that the top qubit rail is that of the coin, and the rest are those of the simulation of the system.

This circuit can be repeated to achieve any number of steps.

```
evolve(n) = shift(n) * coin(n)
YaoPlots.plot(evolve(4))
```

Figure 2.6.: Quantum walk evolve circuit

### 2.3.2.6. Prepare circuit

While we can already simulate the walk, an very useful helper function that we can define is the prepare circuit.

Quantum registers are often initialized to the 0 state, and it is also easy to restart the walk from the 0 state. However, we often like to start the walk in the center of the chain instead of at node 0. Also, the coin is preferred to be in the  $\frac{1}{\sqrt{2}}(|0\rangle + i|1\rangle)$  when we start so that the walk proceeds symmetrically<sup>18</sup>.

Hence, to perform these steps, we define the following `prepare` subroutine.

```
prepare(n) = chain(
    n+1,
    put(1⇒Yao.H),
    put(1⇒Yao.shift(-π/2)),
    put(n+1⇒X)
)

YaoPlots.plot(prepare(3))
```

Figure 2.7.: Initial state preparation circuit

Plotting the walker distribution as before (Figure 2.8), we see that the two implementations are equivalent.

## 2.4. Properties of the walk

Similar to the classical random walk, the mean  $\mu(t) = 0$ .

However, a more interesting feature is that the standard deviation  $\sigma(t) = 0.54t^{18}$ . Compare this with the classical random walk, the quantum walk has a quadratic speed up. This the reason for the quadratic speedup commonly seen in the Grover search and other Monte Carlo problems.

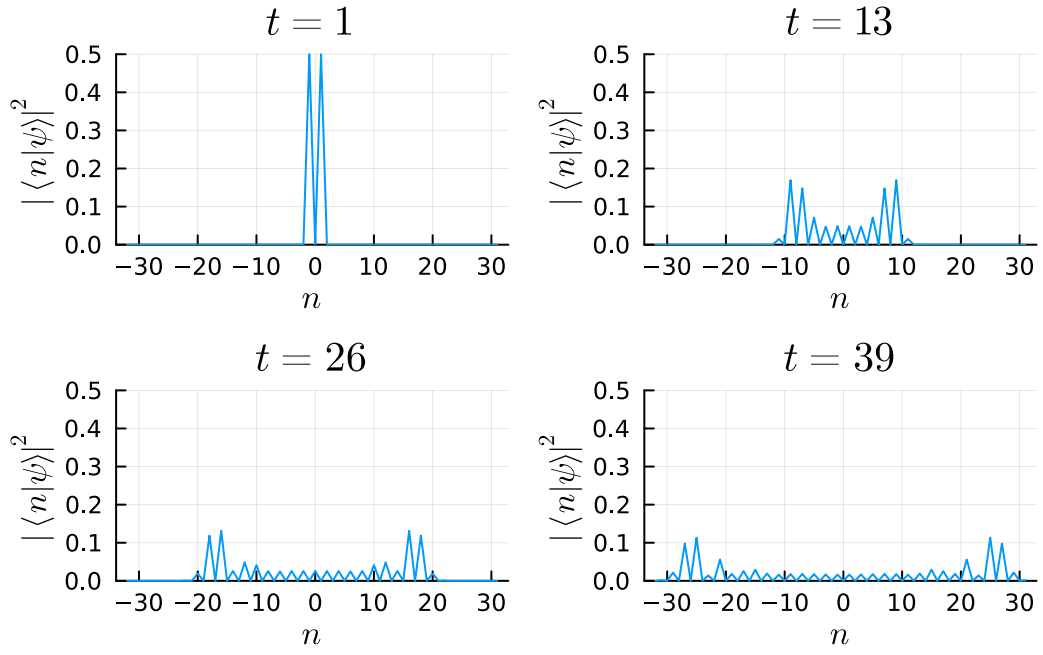

Figure 2.8.: Quantum walk using circuit formalism

Figure 2.9.: Standard Deviation with time for the quantum(*crosses*) and classical random(*circles*) walks

## 3. Search Algorithms

A common application of walks is in search problems. In search problems, we generally have a black box function

$$f(x) = \begin{cases} 0 & x \in G \\ 1 & x \in G^C \end{cases}$$

where  $G \cup G^C = S$  which is the search space. We are interested in developing an algorithm to output some  $x \in G$  by querying  $f$ .

Naively, one can run a stochastic process over the domain  $G \cup G^C$  and observe the system until we see an element in  $G$ . The average time to succeed in this protocol is called the hitting time of  $G$ , and denoted as  $T^G$ . Naturally, we not only want high success rates, but we also want low mean hit times.

In the particular case of Markov chains, hitting times are a kind of stopping time (Appendix A), and are well studied in their own regard.

### 3.1. Formalism

Define the following

- Denote the readout at the  $n^{\text{th}}$  measurement (at  $t = n\tau$ ) as  $X_n$ .
- Select a target node  $\delta$
- Probability of first hit in  $n$  steps  $F_n = P(X_n = \delta | X_i \neq \delta \forall i \in [0, n-1])$
- Mean hit time  $\langle t_S \rangle = \sum_{i=0}^{\infty} i F_i$
- Success probability in  $n$  steps  $S_n = \sum_{i=1}^n F_i = P(\exists i \in [0, n] | X_i = \delta)$
- Survival probability = Failure probability =  $\mathcal{S}_n = 1 - S_n$
- Asymptomatic versions of these terms are given by taking  $n \rightarrow \infty$

#### 3.1.1. Readout in Walks

To identify whether a walker has hit the target node, we need to track the location of the walker as it evolves in time.

For the classical case, this poses no problem, as measurement does not disturb the system. In the quantum case however, we need to be a bit more careful.

A constantly measured walker will freeze the dynamics of a quantum walker. This is known as the Quantum Zeno effect. The solution for this is to measure after every  $\tau$  steps.

### **i** Reduction to classical random walk with $\tau = 1$

The quantum  $\tau = 1$  case reduces the discrete time quantum walk to a classical random walk with  $\tau = 1$ . Effectively, we apply a dephasing operator on the density matrix, dropping all off diagonal terms. Thus, we lose all effects of superposition, causing the classical random walk.

Let us plot the readout trajectories of walkers with different parameters

Figure 3.1.: Trajectories of readouts in quantum and classical walks

Note the very clear difference in the spread between the classical readout and the quantum readout for same  $\tau$ . Similarly note the spread between the quantum readouts for different  $\tau$ s.

## 3.2. Markov Chains and Walks

In the classical case, it is clear that the 1D SSRW is a Markov process. In Appendix B, we show that the quantum walk with measurement is also a Markov process. Consequently, we can use certain results from the theory of Markov processes to compare the two walks.

### 3.2.1. Irreducibility and Recurrence

Under the usual definition of irreducibility (Appendix A), it is trivial that in the 1D chain,  $n = m = |i - j|\tau$  satisfies the condition. It is a well known fact that the 1D SSRW is recurrent. It is just as well known a fact that the 3D SSRW is transient<sup>1</sup>.

In the quantum case, it is not as clear whether any of the available definitions of the quantum Markov process is more or less better than the others. Thus, the transience of quantum walks depends on the exact definition we are working under<sup>19</sup>. In our definition however, it can be shown using symbolic computation<sup>20</sup> that the walk is indeed transient. This poses an interesting problem.

## 3.3. Survival probability

We can thus measure and plot the  $S_n - n$  curve for the quantum and classical walks to compare the efficiency of these walks in the first hit problem.

In previous work<sup>21</sup>, the analytical solution of the success rate as a function of time is found. An analytical result for discrete time walks is harder due to the nature of the walk. However we reproduce the results for the discrete time case computationally. Figure 3.2a<sup>21</sup> shows the success rate for the continuous time quantum and classical walks, and Figure 3.2b and Figure 3.2c shows our results for the discrete time case.

### 3.3.1. Observations

In the *continuous time* case:

- The quantum walk has a fast rise in the initial phase but saturates at  $\sim 0.1$
- The classical walk has a slow rise, but eventually reaches 1

In the *discrete time* case, solved computationally:

- Both walks do eventually reach 1
- The quantum walk shows a saturation for a while before suddenly rising again
- The classical walk shows a slow rise in the beginning phases, in contrast to the sharper rise of the quantum walk.

The observations in the continuous time case can be explained by the recurrence of the walk. While the quantum walker is faster (See Chapter 2), the transient nature (See Section 3.2.1) of the walk leads to a non zero asymptomatic failure rate. Clearly this is a problem. What this means practically, is that for the first hit problem, if the quantum walk hits the target node, it does so faster than the classical walk, but a majority of the times, it doesn't hit the target node at all.

There seems to be an apparent difference between the discrete and the continuous time walks, but this is only an artifact of the finite size of the walk space. It is well known that any irreducible finite chain is recurrent<sup>22</sup>. This claim can be verified by simply increasing the size of the state space, and noting that the saturation phase in the quantum walk lasts longer.

(a) Success probability vs Time for both walks<sup>21</sup>

(b) Success probability vs Time for both walks  $\tau = 4$  (c) Success probability vs Time for both walks  $\tau = 8$

Figure 3.2.: Success Probability

## 4. Stochastic Resetting

The crux of the matter is this. The quantum walk is fast in the initial phase, but eventually saturates asymptotically to a success rate of  $< 1$ . This means that some of the walkers hit the target, and others do not. If that is the case, is it possible to restart the walk when it starts saturating? That is, can we restart the walk for the walkers that have not yet hit the target after  $r\tau$  time?

For such dynamics, we will need to reformulate the walk slightly.

### 4.1. Formalism

A reset of the walker (classical or quantum) implies that the walker returns to its initial state, and the walk dynamics continue from there.

However, we can vary when we reset the walker by considering multiple reset processes. A common reset process is the Poisson reset, where the reset times are modelled as a Poisson process with some parameter  $r$ . This is particularly convenient in the case of continuous time walks<sup>23</sup>.

For the discrete walks, the geometric distribution is more natural.

$$t \sim \text{Geom}(\gamma)$$

, that is, at each step, there is a  $\gamma$  probability of reset. This results in different dynamics, which can be seen in subsequent subsections, but it has an equally drastic effect on the recurrence of the walk.

#### 4.1.1. Recurrence and Resetting

In the geometric resetting case, it is clear that  $P_{00}^n \geq \gamma$ , and hence  $\sum_n P_{00}^n \geq \sum_n \gamma$  which diverges as  $n \rightarrow \infty$ . Thus regardless of the initial walk, the final walk will definitely be recurrent. Thus the motivation for resetting the quantum walk which is transient should be immediately clear.

### 4.1.2. Stochastic Reset Classical Walk

In the classical case, the transition probabilities change to

$$p_{ij} = \begin{cases} (1 - \gamma) \cdot 1/2 & |i - j| = 1 \\ \gamma & j = r_0 \\ 0 & \text{otherwise} \end{cases}$$

Thus, the new transition matrix is modelled as

```
γ = 0.2
U1 = sparse(SymTridiagonal(fill(0., 31), fill(0.5, 30)))
R = fill(0., (31, 31))
R[21,:] .= 1
U = sparse((1-γ) * U1 + γ * R);
```

where U1 is the unchanged walk matrix and R is the reset matrix.

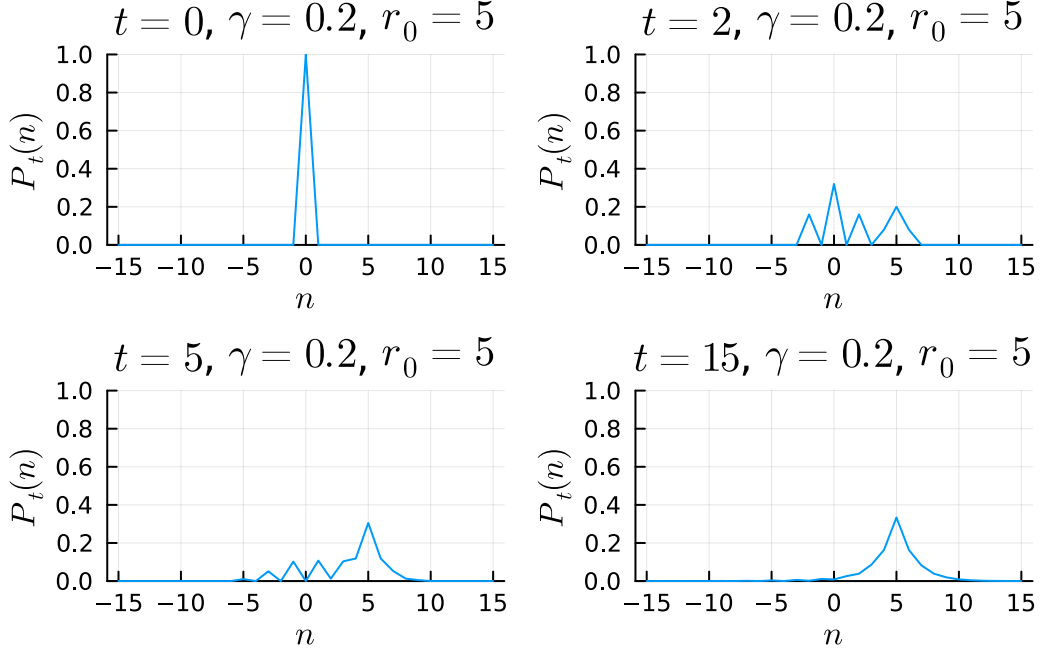

Figure 4.1.: Stochastic Reset Classical Walk

### 4.1.3. Stochastic Reset Quantum Walk

In the quantum case, the evolution changes from unitary dynamics to a non-unitary CPTP map of the following form.

$$O_{SR}(\rho) = (1 - \gamma) (U\rho U^\dagger) + \gamma |r_0\rangle\langle r_0|$$

where  $U$  is the walk unitary.

```

function swqw(n, γ)
    R = collect(Tridiagonal(fill(1., n), zeros(n+1), zeros(n)))
    R[1, end] = 1
    L = collect(Tridiagonal(zeros(n), zeros(n+1), fill(1., n)))
    L[end, 1] = 1
    U = KrausOperators(
        [sparse(proj(ket(1, 2)) ⊗ L + proj(ket(2, 2)) ⊗ R)]
    )
    init_coin = 1/√2 * (ket(1,2) - 1im * ket(2,2))
    H = KrausOperators([sparse(hadamard(2)⊗I(n+1))])
    init_state = proj(init_coin ⊗ ket(n÷2 + 1, n+1))
    ψ = [[init_state]; accumulate(1:40, init=init_state) do old, _
        (1-γ)*H(U(old)) + γ*proj(init_coin ⊗ ket(n÷2+6, n+1))
    end]
    map(enumerate(real.(diag.(ptrace.(
        ψ, Ref([2, n+1]), Ref([1])
    ))))) do (t, ps)
        Plots.plot(
            -n÷2:n÷2, ps,
            ylims=(0, 1), xlabel="\$i\$",
            ylabel="\$\\langle i | \\psi \\rangle\$",
            title="\$t=\$(t), \\gamma=\$(γ), r_0 = |5\\rangle\$",
            legend=false
        )
    end
end;

```

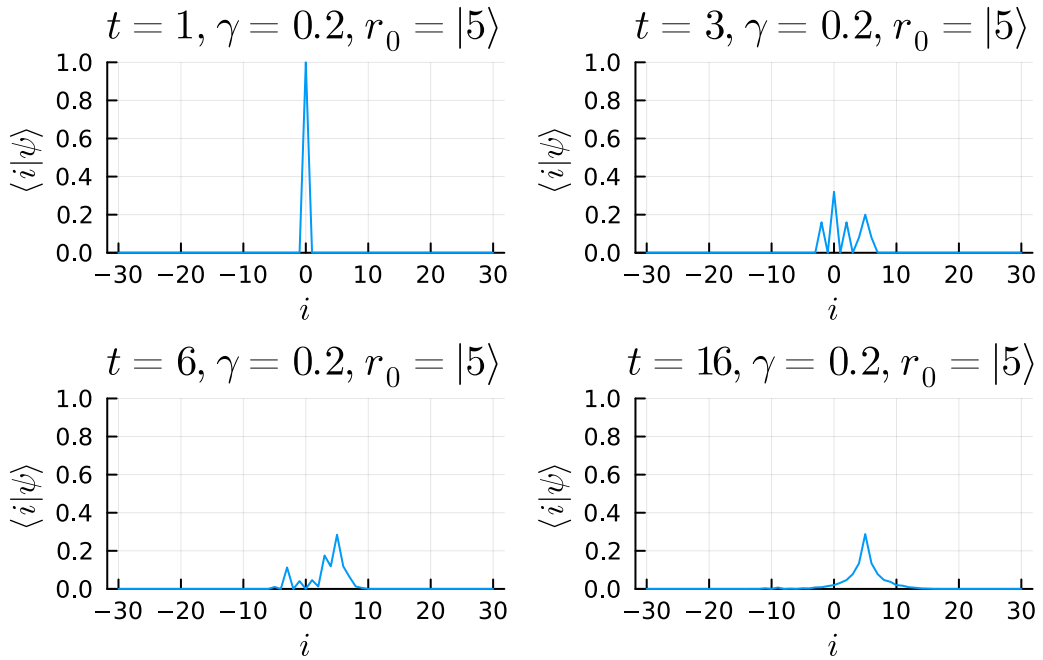

Figure 4.2.: Stochastic Reset Quantum Walk

## 4.2. Effect of Resetting on First Hit problem

For this analysis, we will consider the simpler “sharp reset” formalism<sup>21</sup>, where the reset time is sampled from a distribution

$$t_r \sim \delta(t - r\tau)$$

Thus we restart after  $r$  measurement events (at  $t = r\tau$ ). Once we understand the effect of this kind of reset, gaining intuition for reset times sampled differently is easier.

The success probability versus time can now be plotted (Figure 4.3a)<sup>21</sup> for the reset case.

Now we see that the success probability is drastically increased for both cases, but due to the ballistic nature of the quantum walk, we see that the reset quantum walk performs much better than the classical walk.

For a better understanding of the performance of the reset quantum walk with reference to changing reset rates ( $r$ ) and measurement times ( $\tau$ ), we can plot (Figure 4.3b)<sup>21</sup> the mean first hitting time versus these parameters.

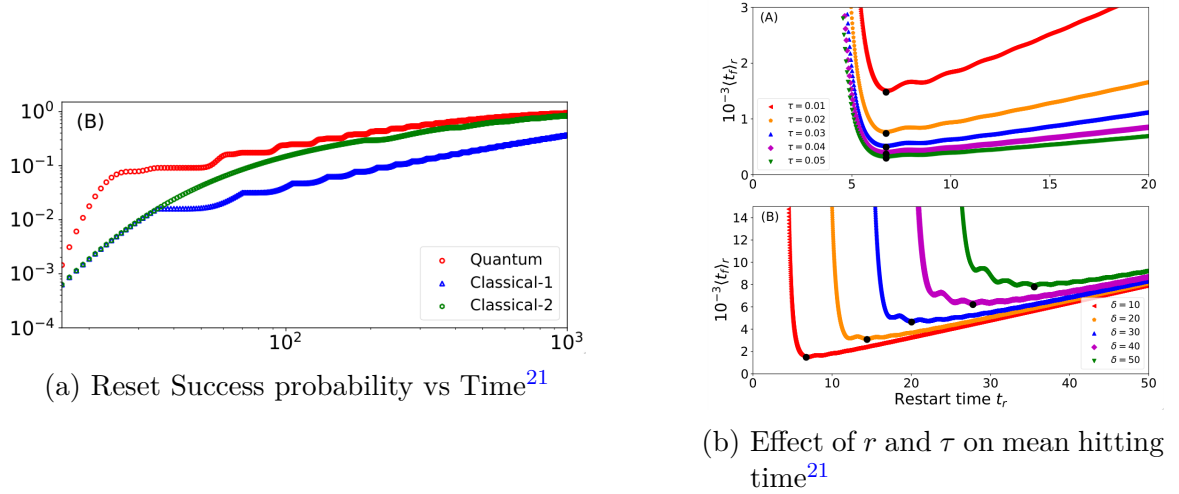

Figure 4.3.: Sharp Reset Quantum Walk

### 4.2.1. Observations

- Deterministic restart leads to zero asymptomatic failure rate
- Eager restarting leads to walker never reaching  $\delta$ , reducing success rates drastically
- Cautious restart reduces the effect of restart, reducing success rates.
- There exists an optimal  $r$ , but this needs to be optimized, which is non trivial for general  $\tau$  and graph structures.

**i** Can stochastic restarting be better than sharp reset?

No, because even if  $\langle r \rangle = r_{\text{optimal}}$ ,  $\langle t_f \rangle > \langle t_f \rangle_{\text{optimal}}$  due to the non-monotonic nature of the curve

### 4.3. Sharp Reset for Discrete time walks

For discrete time walks, the sharp reset walk is given by

$$|\psi_t\rangle = U^{t-r_l\tau}(|c_{\text{init}}\rangle \otimes |0\rangle)$$

where  $r_l\tau$  was the time of last reset.

Equivalently, in the circuit model, the reset circuit is considered to be a measure followed by post process where we apply the appropriate unitary rotation to rotate to  $|\psi_0\rangle$ .

Figure 4.4.: P(hit) vs Time

Figure 4.5.:  $\langle T_{\text{hit}} \rangle$  vs  $r$

Figure 4.6.: Sharp Reset Quantum Walk - Multiple Sampling

Our results are plotted in Figure 4.6 where the circuit formalism is run multiple times, and in Figure 4.11, we pick the diagonal term from the matrix formalism as the infinite limit. Note the similarity between the continuous and discrete curves. However, also note the difference between the non reset curve, where in the discrete case, success probability still reaches 1, this can be attributed, as before, to the finiteness of the walk space.

### 4.4. The Problem in the Solution

As discussed before, reset rates which are very high or low can end up being detrimental to the success times of the walk. Secondly, there is no clear path as to how to optimize the reset parameter for arbitrary graph structures.

Just as we harnessed the power of quantum superposition to speed up the walk, can we similarly have a superposition between the reset and evolution to increase the efficiency of hitting a node?

Figure 4.7.:  $P(\text{hit})$  vs Time  $\tau = 4$

Figure 4.8.:  $\langle T_{hit} \rangle$  vs  $\gamma$   $\tau = 4$

Figure 4.10.:  $\langle T_{hit} \rangle$  vs  $\gamma$   $\tau = 8$

Figure 4.11.: Sharp Reset Quantum Walk - Smooth Sampling

## 5. Quantum Resetting by Superposition

From the previous discussion, it seems fruitful to consider a quantum reset of quantum walks. The concept is similar to that of the quantum walk vs classical walk: let the resetting occur on probability amplitudes rather than probabilities, allowing for useful interference.

For this, we suggest the following formalism

### 5.1. Formalism

On a finite 1D chain of length  $2N + 1$ , define the following -

- Reset operation -  $\mathcal{R}$  by the Kraus operators  $\{\mathcal{R}_i = |r_0\rangle\langle i|\}_{i \in [-N, N]}$  on  $\mathcal{H}_W$
- Evolve operation -  $\mathcal{U}$  by the unitary operation  $S \circ H$  on  $\mathcal{H}_C \otimes \mathcal{H}_W$
- Attach another two level coin - states denoted by  $|0\rangle$  and  $|1\rangle$ . Resulting state lies in  $\mathcal{H}_R \otimes \mathcal{H}_C \otimes \mathcal{H}_W$
- Controlled reset operation -  $\mathcal{E}$  by the Kraus operators  $\{\mathcal{E}_i = |0\rangle\langle 0| \otimes I_2 \otimes \mathcal{R}_i + \frac{1}{\sqrt{N}}|1\rangle\langle 1| \otimes \mathcal{U}\}_{i \in [-N, N]}$ . See Appendix C for proof that this set of Kraus operators represents a CPTP map.
- A reset coin operator  $\Gamma(\gamma) = \begin{bmatrix} \sqrt{1-\gamma} & \sqrt{\gamma} \\ \sqrt{\gamma} & -\sqrt{1-\gamma} \end{bmatrix}$  on  $\mathcal{H}_R$
- One step of the resulting walk is defined as  $\mathcal{E} \circ (\Gamma \otimes I_2 \otimes I_{2N+1})$
- Once again, the hitting protocol is found by measuring the walker position after  $\tau$  time steps.

The initial motivation for such a formalism comes from Anubhav's<sup>23</sup> master thesis, where a similar formalism was applied to a qubit system. The dominant motivation is the faster convergence in the quantum case, which was confirmed in the qubit case. However, the current problem we are considering has drastically changed the methods of exploration and the property we want to optimize.

#### 5.1.1. Interpretation of $\gamma$ and dependence on initial condition of the coin

In the stochastic resetting  $\gamma$  is understood as the “rate” of resetting. However, this is no longer accurate for the quantum case. Consider the case for  $\gamma = 0$ . Then, the

Gammamard operator  $\Gamma = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$ . This does not automatically imply that the reset never occurs; we also require that the initial state of the reset coin is  $|0\rangle$ . If the initial state of the reset coin is  $|1\rangle$ , this corresponds to the always reset case. Thus,  $\gamma$  is better understood as the probability that given the last step was a reset, what is the probability this step is an evolve, and vice versa. Thus, it is not immediately obvious how we can compare the reset mechanisms for a given  $\gamma$ . Nor is it obvious how the initial state of the reset coin finally affects the success probability and such, and needs to be numerically checked.

### 5.1.2. Resetting of the walker coin

In our specific formalism (Section 5.1), we have only applied the reset operation on the walker  $\mathcal{H}_W$ . One could also reset the walker coin  $\mathcal{H}_C$  and see what happens. In our current formalism, there is no entanglement broken between the two coins, but there is no a priori understanding of how this may (or may not) affect the walk.

## 5.2. Computational Implementation

Implementations of  $\mathcal{U}, U, H$  follow as before. The  $\mathcal{E}$  operation is implemented as

```
function E(n, r0)
    ks = map(1:n) do i
        (1/sqrt(n) * [1 0; 0 0] * (S(n)*H(n))) +
        [0 0; 0 1] * I(2) * real(ket(r0,n)*bra(i,n))
    end
    return KrausOperators(sparse.(ks))
end;
```

The gammamard operation  $\Gamma$  is defined as

```
Gamma(gamma) = [
    sqrt(1-gamma)  sqrt(gamma);
    sqrt(gamma)    -sqrt(1-gamma)
];
```

We take the initial reset coin to be  $(S(-\pi/2) \circ \Gamma(\gamma))|0\rangle$  for the same reason as in the quantum walk

```
reset_init(gamma) = [1 0; 0 -1im]*gammamard(gamma)*ket(1, 2);
```

## 5.3. Results

### 5.3.1. What the walk looks like

For the specific choice of initial reset coin as  $1/\sqrt{2}(|0\rangle - i|1\rangle)$  and  $\gamma = 0.2$ , the quantum reset walk looks like Figure 5.1.

Figure 5.1.: Quantum Reset Walk

## 5.4. Results and Discussion

As discussed in Section 5.1.1, we need to vary the three parameters,  $(\alpha, \phi, \gamma)$ , and see what happens. Thus we plot the success curves for a few sets of parameters (Figure 5.2), and find the minimum mean time of hit for each fixed parameter (Figure 5.3).

As we can see, the mean time of hit even for the best set of parameters (within the ranges explored) is not better than the optimal time for the stochastic reset protocol.

### 5.4.1. Optimal Parameter Values

(a) Parameter set 1

(b) Parameter set 2

(c) Parameter set 3

(b)  $\alpha$  vs  $\gamma$

(c)  $\phi$  vs  $\gamma$

Figure 5.3.: Optimal values by fixing the other two parameters

Table 5.1.: Optimal Parameter Values

$\alpha$	$\phi$	$\gamma$
0.0	0.0	$10^{-5}$

### 5.4.2. Drawbacks of the Formalism

The drawback of this formalism is its complexity. Whereas when we defined a quantum walk with a unitary evolution, we now have a complicated CPTP map to analyse. The difficulty doesn't only lie in analytical complexity, but also in simulations, where simulating the quantum reset quantum walk takes much longer. Due to this, we look for a simpler, more elegant model for quantum resetting, preferably one which is unitary supported by a formal protocol to analyse its efficacy.

## 6. Quantum Markov Chains

As suggested in the earlier chapter, we would like to define a unitary quantum resetting protocol unitary for analytical and interpretational simplicity. For this, we reconsider our path until now (Figure 6.1). Instead of quantizing the stochastic reset quantum walk via a coin, can we quantize the stochastic reset classical walk directly?

Figure 6.1.: Work until now

### 6.1. Generalized Coined walks

When we quantized walks in Chapter 2, we attached a 2 level coin whose states represented the selected edge, and by putting the coin into superposition, one can apply a superposition of jumps. We would like to quantize walks on arbitrary undirected graphs using the coined walk formalism.

Graphs can be partitioned into two classes, Class 1 and 2, based of the chromaticity of the graph.

### 💡 Edge Chromaticity

The edge-chromaticity of a graph is the minimum number of colors that the edges can be colored with such that no two adjacent edges are similarly colored and is denoted by  $\rho(G)$ .

By Vizing's theorem<sup>24</sup>,  $\Delta(G) \leq \rho(G) \leq \Delta(G) + 1$ , where  $\Delta(G)$  is the max degree of the graph.

Graphs of Class 1 are those where  $\Delta(G) = \rho(G)$  and graphs of Class 2 are the others. Walks on Class 1 graphs can be quantized by the coin - position formalism similar to the one introduced in Chapter 2, whereas walks on Class 2 graphs can be quantized by a walk on the edges rather than the nodes<sup>18</sup>. However, we're still restricted to undirected graphs.

## 6.2. Szegedy Walks

It is known that discrete time Markov chains do not naturally quantize via the coin formalism<sup>25</sup>. Szegedy<sup>25</sup> came up with a formalism to quantize symmetric irreducible Markov chains by using the bipartite double cover of the underlying graph. This was then generalized to ergodic chains by Magniez et al.<sup>26</sup>. What follows is a brief introduction to the generalized Szegedy walks.

### 6.2.1. Formalism

Let  $P$  be the transition matrix of a reversible Markov chain. Let  $P^*$  be the time reversed Markov chain of  $P$ .

For a state  $|\psi\rangle \in \mathcal{H}$ , let  $\Pi_\psi = |\psi\rangle\langle\psi|$ . For a subspace  $\mathcal{K}$  of  $\mathcal{H}$  spanned by a set of mutually orthogonal states  $\{|\psi_i\rangle : i \in I\}$ , let  $\Pi_{\mathcal{K}} = \sum_{i \in I} \Pi_{\psi_i}$  be the projector onto  $\mathcal{K}$  and  $\mathcal{R}_{\mathcal{K}} = 2\Pi_{\mathcal{K}} - \text{Id}$  be a reflection through  $\mathcal{K}$ .

Let  $\mathcal{A} = \text{Span}(|x\rangle|p_x\rangle : x \in X)$  and  $\mathcal{B} = \text{Span}(|p_y^*\rangle|y\rangle : y \in Y)$  be subspaces of  $\mathcal{H} = \mathbb{C}^{|X| \times |X|}$ , where

$$|p_x\rangle = \sum_{y \in X} \sqrt{p_{xy}}|y\rangle; |p_y^*\rangle = \sum_{x \in X} \sqrt{p_{yx}^*}|x\rangle$$

where  $p_{ij}, p_{ij}^*$  are elements of  $P, P^*$  respectively, and  $X$  is the set of nodes,  $Y$  is the set of nodes after duplication.

### 💡 Quantum Markov Chain

The quantized version of the Markov chain  $P$  is defined to be the unitary operation  $W(P) = \mathcal{R}_B \mathcal{R}_A$  and is called the Szegedy walk. Where defined, the Szegedy walk is equivalent to two steps of the Coined quantum walk<sup>27</sup>.

Figure 6.2.: Duplication Process on a graph<sup>18</sup>

### 💡 The Discriminant matrix

For an ergodic Markov chain  $P$  with stable distribution  $\pi$ , we define

$$D(P) = \text{diag}(\pi)^{1/2} \cdot P \cdot \text{diag}(\pi)^{-1/2}$$

as the discriminant matrix.

#### 6.2.2. Properties

1. On  $\mathcal{A} + \mathcal{B}$ , eigenvalues of  $W(P)$  that have non-zero imaginary part are  $e^{\pm 2i\theta_1}, \dots, e^{\pm 2i\theta_l}$ , with same multiplicity.
2. On  $\mathcal{A} \cap \mathcal{B}$ ,  $W(P)$  acts as the identity. The left (and right) singular vectors of  $D$  with singular value 1 span this space.
3. On  $\mathcal{A} \cap \mathcal{B}^\perp$  and  $\mathcal{A}^\perp \cap \mathcal{B}$ , the operator acts as  $-\text{Id}$ . The  $\mathcal{A} \cap \mathcal{B}^\perp$  (resp.  $\mathcal{A}^\perp \cap \mathcal{B}$ ), is spanned by the set of left (resp. right) singular vectors of  $D$ .
4.  $W(P)$  has no other eigenvalues on  $\mathcal{A} + \mathcal{B}$ ; on  $\mathcal{A}^\perp \cap \mathcal{B}^\perp$  it acts as  $\text{Id}$ .

## 6.3. Szegedy Search or the Quantum Hitting Time

Of the many ways to define the search algorithm (refer to Chapter 3 for an introduction) for Szegedy walks, we shall look at two protocols, one which is easy to understand and the other easy to analyse. The original paper by Szegedy<sup>25</sup> proposed the following protocol -

1. Modify the classical Markov chain to make all the marked vertices sinks.

$$p'_{xy} = \begin{cases} p_{xy}, & x \notin G \\ \delta_{xy}, & x \in G \end{cases}$$

2. Define  $W'(P)$  as the quantum Markov chain by the usual protocol.
3. Define the initial state

$$|\psi(0)\rangle = \frac{1}{\sqrt{n}} \sum_{\substack{x \in X \\ y \in Y}} \sqrt{p_{xy}}$$

4. Finally define the quantum hitting time such that

$$F(T) \geq 1 - \frac{g}{n}$$

where

$$F(T) = \frac{1}{T+1} \sum_{t=0}^T \left\| |\psi(t)\rangle - |\psi(0)\rangle \right\|^2; g = |G|$$

Figure 6.3.: Duplication Process of a graph with marked vertex  $x_3$ <sup>18</sup>

Defined by this protocol, the quantum hitting time is quadratically smaller than the classical hitting time<sup>25</sup> for the 1D case.

A later modification<sup>26</sup> defined the search operation via a Grover-like oracle. This was easier to analyse, and the connection between the spectral gap of the discriminant matrix (Section 6.2.1) and the quadratic speedup attained by the walk is clearer. We leave the exact protocol to reference<sup>26</sup>, but only outline the steps.

1. Prepare the initial state  $|\pi\rangle|0^Tks\rangle$ , where

$$|\pi\rangle_d = \sum_{x \in X} \sqrt{\pi_x} |x\rangle |p_x\rangle = \sum_{y \in X} \sqrt{\pi_x} |x\rangle |p_x\rangle$$

2. First apply the Grover oracle

$$\mathcal{G}(|x\rangle_d |y\rangle_d |z\rangle) = \begin{cases} -|x\rangle_d |y\rangle_d |z\rangle, & \text{if } x \in G \\ +|x\rangle_d |y\rangle_d |z\rangle, & \text{otherwise} \end{cases}$$

3. Apply a phase estimation circuit to the quantum walk, repeated  $k$  times.
4. Repeat steps 2 and 3  $T$  times.
5. Observe the first register, by a projective measurement in the computational basis. Denote by  $\bar{x}$
6. With high probability, output  $\bar{x}$  lies in  $G$

If the eigenvalue gap of the Markov chain is  $\delta$ , and  $\frac{|G|}{N} \geq \epsilon \geq 0$ , the cost to perform this circuit is of order  $\left(\frac{1}{\sqrt{\epsilon\delta}} \log \frac{1}{\sqrt{\epsilon}}\right)$  calls to the walk operation<sup>26</sup>. Contrast this with the classical search which requires  $\frac{1}{\delta\epsilon}$  steps of the Markov walk, we see the quadratic speedup<sup>1</sup>.

Therefore, one can find the spectral gap  $\delta$  of  $P$  and compare the search speed of two chains. This Szegedy formalism beautifully sets up the stage for a truly unitary quantum reset quantum walk protocol which can be analysed for any graph structure without having to resort to simulation techniques.

---

<sup>1</sup>Technically, this is not a quadratic speedup due to the extra  $\log \frac{1}{\epsilon}$  term, and it was only later shown<sup>28</sup> using a protocol of eigenvalue estimation.

## 7. Unitary Quantum Reset Quantum Walk

Armed with the Szegedy formalism from the previous chapter, we can define the unitary quantum reset quantum walk by quantizing the stochastic reset classical walk (Section 4.1.2). It is obvious that the stochastic reset classical walk is not symmetric ( $p_{i0} \neq p_{0i} \forall i \neq 0$ ), so we cannot use the original Szegedy walk, but we can use the generalized Szegedy formalism if we show that our process is ergodic.

### 7.1. Ergodicity of the Stochastic Reset Classical Walk

Figure 7.1.: Graph of the Stochastic Reset Classical Walk

To show ergodicity, we need to show that the walk is irreducible, aperiodic and positive recurrent.

Irreducibility follows from the irreducibility of the 1D walk (Appendix A)  $\forall \gamma < 1$ . For the trivial case of  $\gamma = 1$ , the chain is not irreducible, and we cannot use the Szegedy formalism.

Aperiodicity (Appendix A) of the chain follows from the irreducibility of the chain and aperiodicity of node 0 which is obvious due to the existence of the self loop.

Recurrence is obvious from  $p_{00}^{(n)} \geq \gamma \forall i$  and irreducibility. Positive recurrence is harder to show, but we can solve the recurrence relation (Chapter 5).

Thus, the stochastic reset classical walk is ergodic and is a viable candidate for quantization via the Szegedy walk.

## 7.2. Implementation and Results

The implementation of the Szegedy walk is simplified by the use of `QuantumWalk.jl`<sup>29</sup> and `LightGraphs.jl`<sup>30</sup>

WARNING: using `Plots.gr` in module `Main` conflicts with an existing identifier.

First we define a function that returns the underlying graph and the transition matrix

```
MyGraph(n, γ=0.5) =
    let
        temp = CycleGraph(n) ▷ adjacency_matrix ▷ collect
        reset = zero(temp)
        reset[:, n÷2] .= 1
        stochastic = ((1 - γ) / 2) * temp + γ * reset
        temp = sign.(temp + reset)
        DiGraph(temp), sparse(transpose(stochastic))
    end
```

Then we define and run the search algorithm.

```
function run_search_mygraph(n, δ, T, γ)
    graph, stochastic = MyGraph(n, γ)
    qwe = QWSearch(Szegedy(graph, stochastic), [n÷2 + δ])
    first.(measure.(Ref(qwe), execute_all(qwe, T), Ref([n÷2 + δ])))
end
```

`QuantumWalk.jl` uses the Grover-like search algorithm<sup>27</sup>.

```
struct Simulation
    n::Int64
    δ::Int64
    T::Int64
    γ::Float64
    data::Vector{Float64}
    function Simulation(n, δ, T, γ)
        new(n, δ, T, γ, run_search_mygraph(n, δ, T, γ))
    end
end
```

```

end

mean_hit(s::Simulation) = mean(0:s.T, Weights(success(s)))
success(s::Simulation) = accumulate(s.data, init=0) do old, curr
    (1-old) * curr + old
end

```

We can scan over  $\gamma \in [0, 1]$  and plot the mean hit time.

```

res = map(0:0.01:1) do γ
    Simulation.(100, 10, 100, γ)
end;

```

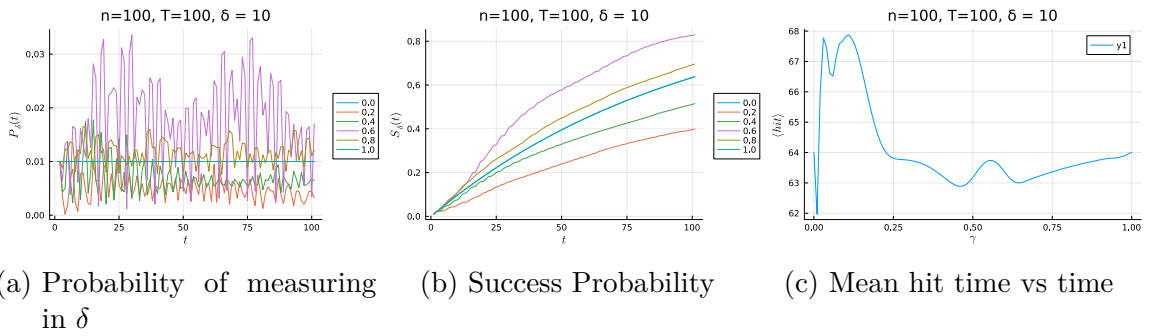

Figure 7.2.: Unitary Quantum Reset

## 7.3. Results and Discussion

### 7.3.1. Exceptional Quantum Walk on the Cycle

For the non reset ( $\gamma = 0$ ) case, we see that the success rate does not increase with time. While this is initially surprising, this is a known result<sup>31</sup>, caused due to the fact that the initial state evolves by phase flips, and the amplitude does not increase.

In the reset case, we see that the walk is no longer exceptional (at least, not in this sense), which allows for an amplitude amplification on the marked node.

### 7.3.2. Mean hitting time vs $\gamma$

Plotting the mean hitting time versus time for 500 nodes and 500 steps, we get the curve in Figure 7.3.

As we can see, there is a clear non-monotonous effect of  $\gamma$  on the mean hitting time of the walk. For values a bit more than  $\gamma = 0.5$ , we see that the mean hitting time is much lower than that for the no reset  $\gamma = 0$  case. Also of note is that as  $\gamma \rightarrow 1$  the mean hitting rate approaches that of the no reset case.

Figure 7.3.: Unitary Quantum Reset

Numerically, the exact time for mean hit changes according to the amount of time that we run the simulation for. This is obvious from the way that the mean hit time is calculated, where if the walk has not succeeded within the time of running the simulation, we assume that it succeeds in the next step. However, we recover the same qualitative curve for large number of steps.

### 7.3.3. Eigenvalue analysis

In Section 6.3, we saw how the quadratic increase in the eigen-gap ( $\Delta P$ ) leads to an associated speedup in the search problem. Thus, if we can show that the eigen-gap increases in for the reset case, we can show that the search protocol requires fewer steps to complete. Furthermore, the space cost of the circuit goes as  $\lceil \log_2 \left( \frac{2\pi}{\Delta P} \right) \rceil$

We see that the transition matrix is extremely sparse, especially for larger system sizes (goes as  $\mathcal{O}(3N)$ , so the density goes as  $\mathcal{O}(1/N)$ ), and that we do not require the entire eigen spectrum to find the eigen-gap. Thus, we can use specialized methods such as the Arnoldi method provided in Julia by the `KrylovKit.jl`<sup>32</sup> package.

```
using KrylovKit

function eigen_gap(M)
    v = real(eigsolve(M, 2, :LR)[1]) # get real(eigval)
    v[1] - v[2]
end

ys = 0.:0.01:(1-0.01)

ΔP = eigen_gap.(getindex.(MyGraph.(512, ys), 2))
```

Figure 7.4.: Analysis by Eigen Gap of the Reset Walk

We see that increasing  $\gamma$  leads to an equal increase in  $\Delta P$ , which corresponds to a faster convergence. However, there is a competing loss of success probability, which is why we see a non monotonic curve for the mean hitting time against  $\gamma$ .

# A. Markov Chains

The following are some definitions related to Markov chains, which can be found in any introductory textbook to the topic<sup>1</sup>.

## 💡 Definition: Connectivity

States  $i, j \in S$ , are connected if  $\exists n > 0, m > 0 | P_{ij}^n > 0$  and  $P_{ji}^m > 0$ . Note that this is an equivalence relation.

## 💡 Definition: Class

If  $C \subset S$ , and  $C$  is closed under Connectivity, then  $C$  is a closed connected class.

## 💡 Definition: Irreducibility

If  $\nexists C | C \subset S$  closed under Connectivity,  $S$  is a closed connected class.

## 💡 Definition: Recurrence

If  $i \in S$ ,  $\sum_{n=1}^{\infty} P_{ii}^n \rightarrow \infty$ , then the state is called recurrent. Equivalently,  $\sum_n F_n \rightarrow 1$  for recurrent nodes. If a chain is irreducible and one of its states is recurrent, all its states are recurrent and thus the chain is called recurrent.

## 💡 Definition: Stopping time

A random variable  $T : \Omega \rightarrow 0, 1, \dots \cup \infty$  is a stopping time the event  $\{T = n\}$  depends only on  $X_0, X_1, \dots, X_n$  for  $n = 0, 1, 2, \dots$

## 💡 Definition: Periodicity

For a state  $i \in S$ , the Period is  $\gcd\{n \geq 0 : p_{ii}^{(n)} > 0\}$ . If the Period of the state is 1, then it is called aperiodic. For an irreducible chain, if one state is aperiodic, then all states are aperiodic, and the chain is referred to as aperiodic.

## 💡 Time reversed Markov chain

For a Markov chain  $P$  with stable distribution  $\pi$ ,  $P^*$  given by  $p_{ji}^* = \frac{\pi_i p_{ij}}{\pi_j}$  is the transition matrix of the time reversed Markov chain.

💡 Definition: Ergodic Markov chain

For a Markov chain  $P$  with stable distribution  $\pi$ ,  $P^*$  given by  $p_{ji}^* = \frac{\pi_i p_{ij}}{\pi_j}$  is the transition matrix of the time reversed Markov chain.

## B. Measured Quantum Walk is Markov

Let  $X_i$  be the  $i$ th readout in the measured quantum walk protocol. This implies that immediately after the  $i$ th measurement, the state of the walker is  $|X_i\rangle$ . After  $\tau$  steps, the walker is in state  $E^\tau|X_i\rangle$ . The probability of measuring the walker in  $X_{i+1}$  is given by  $|\langle X_{i+1}|E^\tau X_i\rangle|^2$ . Thus  $P(X_{i+1} = X_{i+1}|X_i, \dots, X_0) = P(X_{i+1} = X_{i+1}|X_i)$ , which implies that the readouts in the measured quantum walk protocol is a Markov process.

## C. Quantum Reset is a CPTP map

We prove that the set of Kraus operators defined in Chapter 5 form a CPTP map.

We are required to show that

$$\sum_i \mathcal{E}_i^\dagger \mathcal{E}_i = \mathbf{1}$$

We start by evaluating

$$\mathcal{E}_i^\dagger \mathcal{E}_i = |0\rangle\langle 0| \otimes I_2 \otimes \mathcal{R}_i^\dagger \mathcal{R}_i + \frac{1}{N} |1\rangle\langle 1| \otimes I_n = |0\rangle\langle 0| \otimes I_2 \otimes |i\rangle\langle i| + \frac{1}{N} |1\rangle\langle 1| \otimes I_n$$

Summing over  $i$

$$\sum_i \mathcal{E}_i^\dagger \mathcal{E}_i = |0\rangle\langle 0| \otimes I_2 \otimes I_n + |1\rangle\langle 1| \otimes I_2 \otimes I_n = I_{4n}$$

We are done.
